

# COMPARING THE LAST EFFECTIVE BOLL POPULATIONS IN ULTRA-NARROW-ROW AND CONVENTIONAL COTTON

*Earl D. Vories and Robert E. Glover<sup>1</sup>*

## RESEARCH PROBLEM

Identification of the last effective boll population allows informed decisions for termination of insecticide and application of harvest aids. However, the current COTMAN cutout reference, i.e., NAWF=5 (Oosterhuis et al., 1999), may need to be changed for ultra-narrow-row (UNR) cotton. This study is part of a multi-state project which has an overall objective of determining the main-stem node number of the last effective boll population in UNR cotton grown in a range of typical field environments, compared to wide-row cotton in those same environments. This report describes the study conducted in northeast Arkansas in 2001.

## BACKGROUND INFORMATION

A great deal of research has gone into COTMAN, the COTton MANAGEMENT system developed at the University of Arkansas (Danforth and O'Leary, 1998). Comparison with a target development curve (TDC) indicates when the crop is under stress. Identification of the last effective boll population allows informed decisions for termination of insecticide and application of harvest aids. Additional decisions (e.g., irrigation, plant growth regulators, etc.) may soon be linked to observations from COTMAN.

COTMAN relies on empirical data obtained from wide-row cotton (i.e., 30- to 40-inch row spacing) that may not accurately reflect the boll population of UNR cotton (i.e., row spacing <~15 inches). Research in Arkansas indicated that the last effective boll population is set in conventional wide-row cotton when there are five nodes above the highest first-position white flower (NAWF=5) (Bourland et al., 1992). Bolls set above this position (i.e., NAWF<5) are usually too small or too late in maturing to contribute significantly to yield. However, Gwathmey et al. (1999) reported that the

current COTMAN cutout reference (NAWF=5) might need to be changed for UNR cotton. UNR cotton is typically much shorter, with fewer main-stem nodes and fewer bolls per plant than wide-row cotton. Exploratory studies with COTMAN in UNR cotton have produced crop development curves that differ markedly from wide-row cotton and from the COTMAN TDC (Gwathmey et al., 1999; Vories, 2001). A typical UNR curve has a low peak and an abrupt cutout relative to wide-row cotton in the same environment. This suggests that NAWF=5 may not represent the last effective boll population in UNR, which may be set relatively higher on the plant than with wide rows.

Effective late-season management with COTMAN requires accurate identification of the last effective boll population. In addition to the observations with UNR cotton, previous observations of growth curves for conventional cotton (unpublished data) suggest that the natural stresses resulting from growing in clay lead to a development curve different from the COTMAN TDC. Such observations have led to suggestions that a different NAWF value for cutout might be appropriate on those soils. The relatively small amount of cotton produced on such soils has precluded development of a separate TDC. However, if UNR cotton is going to expand cotton acreage, it must do so by allowing production of cotton on soils previously considered “marginal” cotton ground.

## RESEARCH DESCRIPTION

A field study was conducted at the Northeast Research and Extension Center (NEREC) at Keiser on non-irrigated cotton (*Gossypium hirsutum* L. cv. PM 1218 BG/RR) in 2001 on Sharkey silty clay (Chromic Epiaquerts). The experimental design consisted of a randomized complete block with two systems: conventional cotton produced on 38-inch rows (CONV), and ultra-narrow-row cotton produced on 7.5-inch rows (UNR), with six replications. Plots were approximately 50 ft wide by 600 ft long. The CONV plots were planted on beds with a John Deere 1700 planter at a seeding rate of 5 seed/ft, resulting in 41,000 plants/acre; UNR plots were flat planted with a John Deere 750 grain drill and a seeding rate of 2.7 seed/ft, resulting in 115,000 plants/acre. Planting date was 29 May, with imidicloprid (Gaucho)-treated seed. Nitrogen was aerially applied at 128 lb N/acre as urea on both treatments on 2 July.

At first flower, 15 typical plants per plot were flagged for subsequent flower tagging, with all first-position flowers tagged every other day with date and NAWF. White flowers were tagged with the current day's date; pink flowers were tagged with the previous day's date. Tagging continued until 24 August. Plots were defoliated 20 September with a tank mix of 10 oz product/acre tribufos (Def) and 2.0 lb ai/acre ethephon (Prep). The tagged bolls were hand picked and the seedcotton was air-dried before weighing. Plots were machine harvested on 9 October. Eight rows from CONV were spindle picked, while an equivalent width (~25 ft) from UNR was harvested with a cotton stripper with a platform header.

## RESULTS

White flowers were first observed in CONV on 21 July, 53 days after planting (DAP), and in UNR on 23 July, 55 DAP, earlier than the 60 DAP for first flower on the COTMAN TDC (Table 1). The faster flowering was likely the result of waiting until 29 May for planting, after temperatures were warmer than typical for cotton planted earlier in the growing season. A total of 862 flower tags were recovered, with 545 from CONV plots and 317 from UNR plots. Although NAWF on the TDC begins at 9.25 and declines at a rate of 0.2 per day, cotton in this study did not begin at as large a NAWF value and declined faster. Regression analysis indicated a NAWF at first flower of 8.5 for the CONV plots and 6.5 for UNR. The days from planting to NAWF=5 were 67 and 62 DAP for CONV and UNR, respectively, much less than the 80 DAP associated with the COTMAN TDC. However, the late planting date and drought stress probably affected the days to NAWF=5 and possibly the NAWF at first flower.

Lint yields were significantly greater for UNR, with 620 and 540 lb/acre for UNR and CONV, respectively. Three-year average gin turnout values reported by Vories et al. (2001) of 33% and 29% for CONV and UNR, respectively, were used to estimate lint yield because those values were associated with a commercial gin with lint cleaners. However, the NAWF associated with the yield differed between treatments (Fig. 1). Significantly more of the yield was associated with UNR from NAWF = 3 and 4; while more was associated with CONV from NAWF = 5 and 6. Other bolls, primarily second sympodial-position bolls, made up significantly more of the yield for CONV.

The relationship between first-position white flower (hereafter called flower) number per plant and the associated NAWF was quite different between treatments (data not included). No significant differences were observed for  $NAWF \leq 3$ ; however, significantly more flowers were observed for CONV for  $4 \leq NAWF \leq 8$ . No flowers were observed in UNR for  $NAWF \geq 9$ . Flowers per plant can be misleading due to the great difference in stand densities between treatments; therefore, flowers per acre (Fig. 2) may be more indicative. For  $1 \leq NAWF \leq 3$ , there were more flowers per acre for UNR. For  $6 \leq NAWF \leq 8$ , CONV had more flowers per acre. Peak flower numbers were associated with NAWF = 3 and 6 for UNR and CONV, respectively.

Of the 862 flower tags recovered, 444 were associated with whole bolls, with 314 and 130 from CONV and UNR plots, respectively. There was significantly higher retention of flowers with UNR for NAWF = 3 and 4 and with CONV for NAWF = 8 (Fig. 3). Boll size was not significantly different for  $NAWF \leq 6$  (data not included). Bolls were significantly larger for CONV for NAWF = 7 and 8.

## PRACTICAL APPLICATION

UNR plots yielded more than CONV, with 51% of UNR yield associated with NAWF = 3 and 4; 31% of CONV yield was associated with other than first position bolls. These data will be combined with data from similar studies at other locations to

determine whether a different target development curve will be required for COTMAN with UNR cotton. However, with more of the UNR cotton's yield coming from higher in the plant (NAWF<5), these preliminary findings suggest a different curve will be appropriate.
